Guidance and best practices for species identification using eDNA metabarcoding - When do you call a cod a cod?

Abstract

With the rapid uptake of environmental DNA (eDNA) metabarcoding for a wide range of conservation and management uses, there is a growing need for guidance and best practices for species identification. A range of methodological and interpretive decisions influences taxa assignment. Here we provide a review and perspective of pitfalls and issues that can impact accurate taxonomic assignment across the full eDNA metabarcoding workflow; primer selection, lab handling, bioinformatics, taxonomic assignment, and communication of results. This paper addresses the complexities and challenges of the metabarcoding-based species identification process, offering recommendations for robust workflows and effective communication of findings. Accurate interpretation and communication of eDNA metabarcoding results requires an acknowledgment of methodological limitations such as incomplete reference databases, contamination risks, ambiguous sequences, and detection biases. Thus, we argue that transparency of methods and limitations alongside proactive alignment of decisions with project objectives are critical for the successful application of eDNA metabarcoding to conservation and management decisions. We provide guidance for developing protocols that support species identification from eDNA metabarcoding sequences, and give recommendations on communication strategies for stakeholders and end users. To support these recommendations, we outline steps in the workflow that can impact species identification, with a discussion of the strengths and weaknesses at each stage. Ultimately, this guidance can improve the accuracy, reliability, and usability of eDNA species identification while fostering trust and understanding among diverse end users.

Environmental DNA, monitoring, ecosystem, metabarcoding, species identification,

Introduction

The use of environmental DNA (eDNA) for species identification has increased rapidly in recent years. eDNA can provide a non-invasive and sensitive method for detecting species presence, even for rare or elusive organisms (e.g. Takahashi et al. 2023; Bernatchez et al. 2024) Researchers and managers are increasingly adopting eDNA metabarcoding methods to survey biodiversity, monitor invasive species, assess ecosystem health, and inform conservation efforts. Advances in sequencing technology, bioinformatics tools, and reference databases have further facilitated the wider application of eDNA, making it a valuable tool across a range of ecological studies and management applications.

However, accurate sequence-based species identification is complicated by multiple factors, including incomplete reference databases, the inability of some primers to distinguish closely related species based on the target region, differing results based on quality control, dereplication, annotation workflows, and sensitivity to parameter choices such as confidence thresholds (Hleap et al. 2021; Keck et al. 2023). Decisions made at each step will change the level of specificity and sensitivity of the analysis. Careful documentation and reporting of all steps provides transparency and allows users to identify key decision points within the process. These decisions, and implications for use of the data, must be communicated carefully to stakeholders who may be less familiar with eDNA methods.

This paper addresses the complexities and challenges of the metabarcoding-based species identification process, offering recommendations for robust workflows and effective communication of findings. We provide guidance for developing protocols that support species identification from eDNA metabarcoding sequences, and give recommendations on communication strategies for stakeholders and end users. To support these recommendations, we outline steps in the workflow that can impact species identification, with a discussion of the strengths and weaknesses in each stage.

An eDNA metabarcoding workflow begins with project objectives, sample plan design and sample collection, and then moves into extraction, polymerase chain reaction (PCR), bioinformatics, and development of data products. This paper focuses on the post-extraction processes, beginning with primer selection, PCR, and sequencing, then bioinformatics and taxonomic assignment. Finally, we discuss dissemination of results and communication with stakeholders, including the difference between taxonomic assignment and species identification (Figure 1).

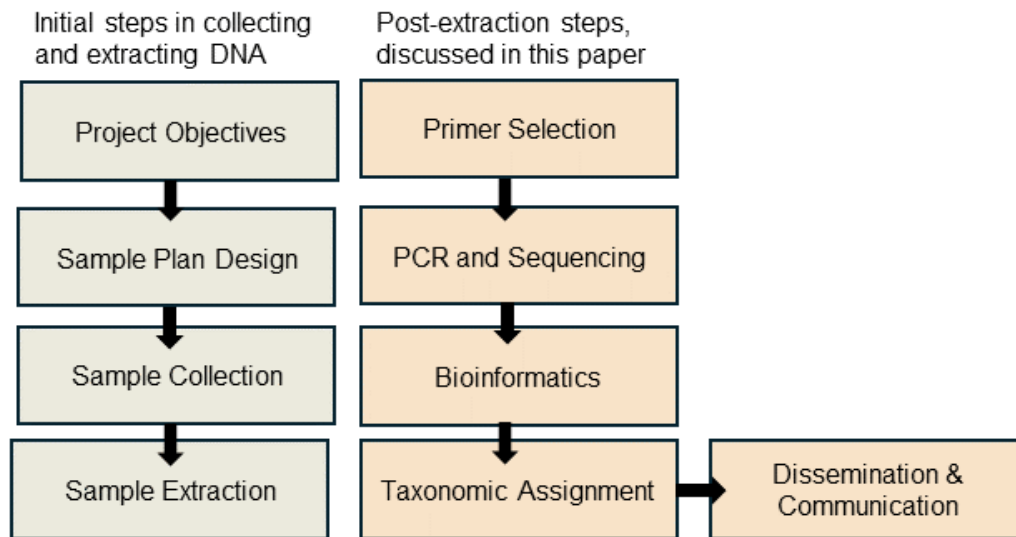

Figure 1. All steps in the metabarcoding workflow potentially affect taxonomic assignment and species identification. In this paper we focus on the post-extraction processes.

Primer selection

Primer choice is the first and most fundamental factor influencing species identification in metabarcoding. Primer selection should be considered early in the project planning process, but at any point, extracted samples may be re-analyzed using a different primer set(s) to meet new or revised project goals. Primers are synthetic oligonucleotides that bind to either end of a target DNA sequence to enable its PCR amplification. Metabarcoding primers are typically used to amplify sequences that are variable among species to maximize species discrimination (Fontes et al. 2024); but conserved at both ends to maximize primer binding and subsequent amplification across many species. The conflicting nature of these two aims, plus other considerations such as reference sequence availability (Ahmed et al. 2019), non-target sequence amplification (Collins et al. 2019), and amplicon length, makes primer choice a complex decision that involves multiple trade-offs. In many cases, a literature search of similar studies in the study area targeting the same species can help identify an appropriate primer set(s).

When selecting primers, we recommend systematically assessing the strengths and weaknesses of candidate primer sets. First, the target species list should be co-developed with the end-user to ensure realistic and clear expectations up front. Candidate primers can then be found in the literature (Zhang et al. 2020) or through communication with other researchers. There are multiple primers developed for specific taxonomic groups that are widely used (e.g., (Miya et al. 2015; Leray et al.

2013; Parada et al. 2016; Amaral-Zettler et al. 2009); in many cases, this review will identify appropriate primer set(s). However, small differences in target species may dictate specific primer choices; for example, *Gadus* (cod) species are difficult to distinguish using the common 12S MiFish (Miya et al. 2015) primer, but can be effectively resolved using the Gadid_ND1 primer (Ledger et al. 2024). Primer sets are also designed with varying levels of specificity from species-focused (e.g., *Sebastes* rockfish) to broad categories (e.g., bacteria). Primers with greater taxonomic breadth generally have less species-level specificity, highlighting a key trade-off in primer selection.

Additional validation can be done through a candidate primer assessment approach, of which there are two general options: *in vitro* and *in silico* testing. *In vitro* testing, which is metabarcoding of specimen tissue voucher-derived DNA extracts, is the most straightforward and accurate way to evaluate primers, but can be costly and challenging to implement if target species tissue or DNA is not readily available. *In silico* primer testing is more cost effective and less logistically challenging, making it the more popular choice. *In silico* primer testing involves gathering reference sequences for target species (from a curated library like BOLD or a public library like GenBank) and then evaluating primer chemistry and sequence alignments computationally. Published tools such as GAPeDNA (Marques et al. 2021), and MultiBarcodeTools (Zhu and Iwasaki 2023) can be used for development of *in silico* validation of metabarcoding primers. Important metrics to consider during *in silico* evaluation include:

- **Reference sequence availability:** How many target species have an available reference sequence for this locus? This will set the limits of your evaluation.
- **Amplification likelihood:** Amplification likelihood of a target sequence by a given primer set can be estimated based on the number, location, and type of base-pair mismatches for given PCR conditions like primer concentration, annealing temperatures, and primer properties such as primer length or GC content. Exact matches between target and primer sequences indicate a high likelihood of amplification. Lower amplification likelihood will result in either reduced amplification rates (termed **primer bias**) or failure to amplify.
- **Amplicon discriminatory power:** To distinguish different species, the amplicon sequence must vary sufficiently. Creating a sequence dissimilarity matrix, multiple sequence alignment, or cluster-based sequence comparisons between all species' amplicon sequences can help assess this criterion.
- **Amplicon length:** While shorter amplicons are preferred for eDNA studies, especially if samples are expected to have degraded DNA, longer amplicons may improve amplicon discriminatory power (Buetas et al. 2024). The reliability and availability of sequencing technologies also influence this decision, with a need to align amplicon length with sequencing technology capabilities. Recent advances

in long-read sequencing technologies have opened the door to longer targets that were previously accessible (Zhang et al. 2020), providing an avenue for enhanced taxonomic assignment from eDNA metabarcoding approaches.

- **Non-target amplification:** Some primers are more/less efficient at amplifying both target and non-target species, regardless of ability to resolve taxonomy. In some cases, amplification of non-target organisms may outcompete and overwhelm signals from the intended targets. Non-target amplification can be mitigated in the lab if target and non-target sequences are of significantly different lengths.
- **Two or more primer sets:** A multi-marker approach, including nested PCR, provides more robust data to support taxonomic identification, but the amount of lab, sequencing, and analysis effort required scales quickly (Lyet et al. 2021; Mahon et al. 2023; Ferreira et al. 2024).

Primer selection will be most effective when integrating information from literature reviews, regional expertise, and both *in vivo* and *in silico* validation. Once the primers have been selected and eDNA samples collected, samples are transported to, and processed in, a designated lab. In some cases, analysis will be conducted by the same team that conducted field work, while in others, samples may be sent to a commercial or collaborating lab (Vasselon et al. 2025). The recommendations below apply to either in-house or outsourced sample processing.

PCR and Sequencing

Samples must be handled with strict contamination control in the lab to ensure accurate species identification (Goldberg et al. 2016). This includes using sterile equipment, processing samples in dedicated clean areas, and including negative controls to detect potential contamination. Improper handling may result in cross-contamination between samples, contamination from external sources, or degraded DNA from poor storage. Failure to adhere to these best practices can lead to false positive detections due to cross-contamination or false negative results from degraded DNA. These errors can ultimately result in inaccurate species lists and misleading ecological interpretations (Darling et al. 2021).

Lab Contamination from Other Tissues/Controls

DNA contamination from non-target tissues or controls can result in false positives or skewed species abundance. Dedicated lab areas with unidirectional air flows, rigorous decontamination (UV, 10% bleach, DNAZap, etc.), the inclusion of negative controls (extraction and PCR blanks) in every batch, and utilization of closed versus open filtration (Patin and Goodwin 2023) reduces chances for contamination. Any high-template positive DNA control stored or present in the lab area should either be from

taxa with no plausible ecological overlap (Stoeckle et al. 2022), or include a synthetic insert sequence (Sepulveda et al. 2020).

Degradation During Handling

Prolonged storage, repeated freeze/thaw cycles, or improper handling can degrade DNA, particularly impacting the detection of rare species. Maintaining samples at -20°C for short term, or -80°C for long term storage, minimizing freeze/thaw cycles (create aliquots before first freeze - e.g., archive, stock, working stock), and regularly assessing DNA quality (have an *a priori* decision on when to throw out stocks, especially if stock is for quantification, such as a qPCR standard) can enhance DNA storage and quality assurance.

PCR Protocol Variability

Even with a standardized primer set, differences in DNA extraction methods and PCR conditions can bias species amplification. For PCR, thermal cycling conditions, choice of polymerase, inclusion of albumin serum, and buffer conditions can increase/decrease primer specificity (e.g., high-fidelity polymerase, single annealing temperature vs. touchdown PCR) (Clarke et al. 2017; Gohl et al. 2016; Baidouri et al. 2025). Detection of large-scale trends and patterns may be less sensitive to specific PCR conditions, but identification of rare amplicon sequence variants (ASVs) or species is more sensitive to methodological differences. Protocols should be standardized and validated with replicates and internal standards, and detailed sufficiently to allow reproducibility.

Sequencing

Sequencing protocols and method details will be driven by sequencing platforms. Several different sequencing platforms can be used for metabarcoding, each with trade-offs. Illumina instruments (like MiSeq, NextSeq, or NovaSeq) are used in many labs and support relatively low cost high-throughput short-read sequencing, though they are limited to shorter amplicons (≤ 500 bp). Other platforms, including Oxford Nanopore devices (e.g., MinION), PacBio, and Ion Torrent, can produce longer reads, although the sample throughput rate is lower, and the bioinformatics may be more challenging due to higher error rates and variable read lengths. Sequencing depth guides the number of reads returned per sample; deeper sequencing (more reads) may be helpful in detecting rare taxa (Singer et al. 2019), where only a few copies of DNA are present in the sample, but the cost of processing generally increases as high read counts are requested. Aligning sequencing choices with primer selection and project objectives is critical to ensure that the generated data meet overall research goals.

Importantly, we note that amplicon libraries are inherently low in diversity which can cause issues on sequencing on platforms such as Illumina MiSeq as high concentrations of the same base on the flow cell can mask less abundant bases during

base calling and clustering steps, resulting in inaccurate base calls for samples, this issue is compounded when using target regions that only amplify relatively low diversity groups (e.g., MiFish, Gadid_ND1 primer). The addition of PhiX (Illumina; 2025) during sequencing alleviates this issue by introducing highly diverse sequences into the run, increasing base calling accuracy and overall run performance. Genomic libraries can also be included in an amplicon sequencing run to contribute sequence diversity and reduce the amount of sequencing effort lost to PhiX control reads. With all 'low diversity' amplicon libraries, a spike of 10-20% PhiX is commonly recommended (Bourlat et al. 2016), although concentration differs across instruments, with NovaSeq and NextSeq instruments often requiring 30-40% (Illumina, 2025).

Bioinformatics

Bioinformatics provides the computational framework necessary to process, analyze, and interpret the large amounts of DNA sequence data generated by eDNA studies. Through a combination of sequence quality control, error detection, taxonomic assignment, and statistical analysis, bioinformatic methods enable researchers to transform raw sequence reads into reliable information on species presence, community structure, and ecological patterns. Robust bioinformatic pipelines are essential to ensure accuracy and reproducibility of eDNA-based biodiversity assessments and facilitate comparisons across studies and ecosystems. Decisions are made throughout a pipeline that impact results in multiple ways. We do not provide recommendations for specific software or pipelines but rather offer guidance on those aspects of the methods that are particularly important for species identification. We note that in some cases, a taxonomy-free approach may better serve project goals (e.g., if measuring overall biodiversity), and in these projects, taxonomic assignment guidelines are less relevant. But in cases where a primary goal requires identifying a specific species or community, the bioinformatics pipeline is a crucial part of the process. We generalize bioinformatic workflows into two main steps: 1) quality control and dereplication, and 2) taxonomic assignments.

Sequence Quality Control & Dereplication

Quality control of sequence reads is a key step in any bioinformatic pipeline to remove errors that are generated by laboratory and sequencing processes. These errors can lead to incorrect species identification and inaccurate assessments of biodiversity. Errors are first addressed by filtering and trimming low-quality or off-target reads from raw reads using sequence quality score thresholds (Figure 2A). Quality filters apply models to base-call quality scores to estimate the likelihood of sequencing errors. Threshold selection should be informed by previous experiments and sequencing run quality. Additional trimming of sequences is often conducted when removing primers, indices, and adapters, either using fixed-length or targeted sequence alignment-based approaches. Incomplete removal of indices, sequencing adaptors, or primers can alter

the resulting sequences, often due to the inclusion of degenerate bases. Thus, filtering and trimming choices can influence which sequences are retained for dereplication and taxonomic assignments, and which species are identified.

Quality-controlled reads are then dereplicated to identify putative unique sequences or sequence clusters and reduce the computational load of redundant taxonomic comparisons. There are two main strategies for dereplicating amplicon sequence reads: cluster-based algorithms and denoising algorithms (Figure 2B). Cluster-based algorithms rely on sequence similarity to generate Operational Taxonomic Units (OTUs), whereas denoising approaches use read frequency and sequence composition-based inference of likely sequencing errors to generate amplicon sequence variants (ASVs) (Quince et al. 2011). Choice of percent similarity thresholds in clustering algorithms greatly affects the resulting OTU composition and thus taxonomic assignments (Robert C Edgar 2018). Likewise, algorithmic choices in denoising pipelines can influence the downstream ASVs retained. For example, DADA2 models the relationship between sequence error rates and quality score for each individual sequencing run, whereas Deblur uses a consistent set of error rates derived from experiments (Amir et al. 2017). Lastly, additional quality control steps in the dereplication process can be applied to remove sequencing errors (e.g. chimeric sequences). If sequencing errors pass the denoising step, they may be counted as a unique, low-frequency ASVs, and pervasive artifact ASVs can reduce the relative estimated abundance of taxa (Irber et al. 2024).

Together, algorithm and parameter choices in the quality control and dereplication steps affect which sequences are retained in the dataset, ultimately influencing which species are or are not detected from eDNA metabarcoding.

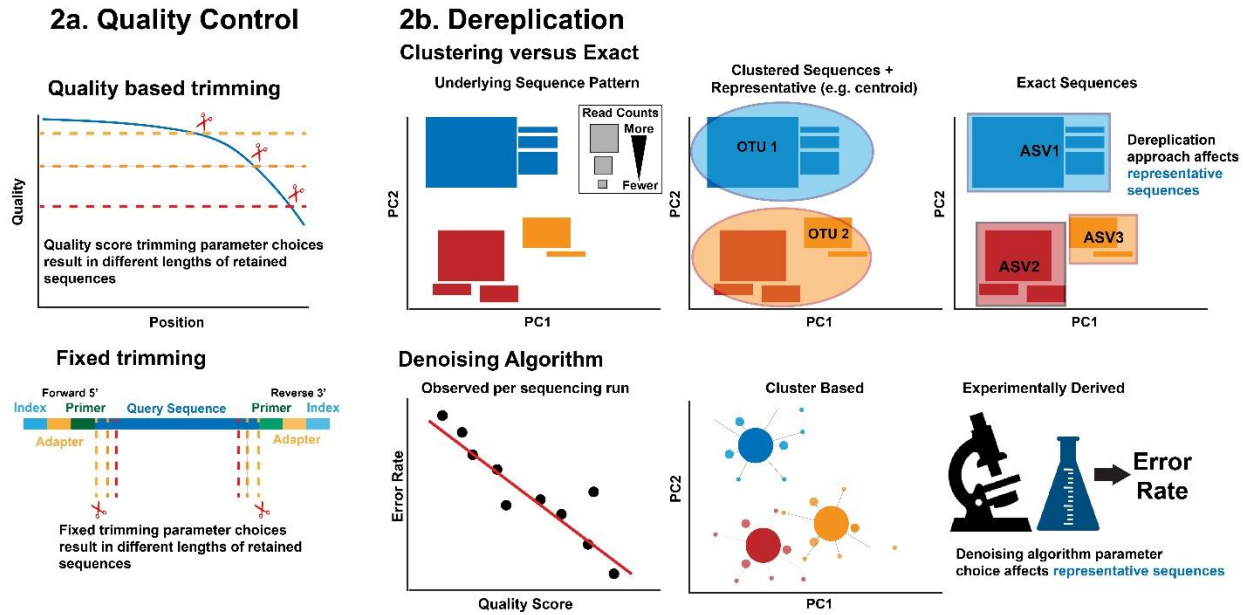

Figure 2: Quality control and dereplication influence underlying reference query sequences and thus have downstream implications on taxonomic assignments. Trimming approaches are either based on quality scores or fixed length, which can influence the length and accuracy of retained sequences (2A). Dereplication approaches also impact which sequences are retained from metabarcoding. There are two main dereplication strategies (2B), clustering by percent sequence identity (e.g., Operational Taxonomic Unit) or by exact or amplicon sequence variants (ESV/ASV). Denoising algorithms are used to indicate likely sequencing errors. The underlying algorithm and parameter selection can influence which sequences are retained.

Dealing with ASVs: Signal or Noise?

The increasing use of ASVs instead of OTUs in eDNA metabarcoding has improved taxonomic resolution and reproducibility, but has also introduced new considerations for bioinformatic filtering and interpretation (Callahan et al. 2017; Chiarello et al. 2022). Unlike OTUs, ASVs retain exact nucleotide sequences, making it crucial to carefully separate true biological variants from sequencing artifacts. Rare ASVs, in particular, present challenges as they can represent genuine rare species or populations, PCR errors, sequencing errors, contamination, or technical artifacts like PCR chimeras or index-hopping (Alberdi et al. 2018; 2018; Stoeckle et al. 2024). Decisions regarding retention or exclusion of rare ASVs should thus balance sensitivity to real biological diversity against the specificity needed to prevent false-positive detections. Common strategies include applying abundance or prevalence thresholds (e.g., retaining ASVs

above a relative abundance of 0.1%), requiring replicate confirmation, or employing occupancy modeling to evaluate detection consistency across technical replicates (Kelly et al. 2019; Gold et al. 2021). Incorporating post-denoising curation tools, such as the LULU algorithm, can further improve data quality by merging spurious sequences based on similarity and co-occurrence patterns without excessively removing rare, potentially informative taxa (Frøslev et al. 2017). Transparent documentation of these filtering criteria and rationales is essential to ensure reproducibility, facilitate cross-study comparisons, and clearly communicate the reliability of rare ASV detections.

Taxonomic Assignment

Accurate metabarcoding results rely on the detection of biologically valid sequences and the correct taxonomic assignment of those sequences. There are several methods of assigning taxonomy to amplicon sequences, with the two most common categories being alignment-based and *k*-mer based methods (Hleap et al. 2021). Alignment-based methods, such as BLAST (Boratyn et al. 2013) and vsearch (Rognes et al. 2016), compare sequences base-pair-by-base-pair to determine observed sequence similarity to reference sequences. Alignment “quality” or score is based on both coverage of the query sequence against the reference sequence as well as the number of matching base pairs within the covered regions (Figure 3A). Thresholds can then be applied to both of those parameters to establish cutoffs for accepted alignments. Such thresholds can be adjusted for different taxonomic ranks (e.g. species, genus, family) and should be based on the marker gene composition, marker gene inter- and intra-specific variability, marker gene length, and target taxonomic group. For example, a common threshold for species-level assignment of the 12S rRNA gene (MiFish region) to species level is 97-98% (e.g., Polanco F. et al. 2021; Sales et al. 2021). However, even within one marker gene and one target organism group, the identity threshold can vary widely among clades (Bokulich et al. 2018; Edgar 2018; Curd et al. 2019; Gold et al. 2021; Polanco F. et al. 2021). If a sequence does not align to any reference sequence at or above the specified threshold level, indicating the observed query sequence is not represented in the reference database, a lower threshold (e.g., 95%) for generic level assignment can be used for assignment to a higher taxonomic level, such as genus or family (NOAA PMEL et al. 2023), although the appropriate threshold varies by marker, taxon, and project goal.

A second or complementary strategy to alignment-based taxonomic assignment is phylogenetic-based assignment. Here reference sequences are first aligned in a multiple sequence alignment and then used to construct large marker gene-specific phylogenetic trees (Figure 3B). ASVs are then assigned based on their closest tree-based reference. Examples of phylogenetic-based classifiers include *tronko* (Pipes and Nielsen 2024a), *EPA-NG* (Barbera et al. 2019), and *pplacer* (Matsen et al. 2010).

Phylogenetic approaches have been shown to be particularly helpful for placing sequences that lack exact matches in reference sequence databases, as they provide confidence scores for every node of the tree. In general, more conserved genes with reliable rates of mutation over evolutionary time will produce more accurate phylogenetic placements, as will markers with lower rates of divergence and longer sequences (Dunthorn et al. 2015). In addition, the methods used to build multiple sequence alignments and conduct phylogenetic placement will influence taxonomic assignments.

A major challenge of implementing phylogenetic-based approaches is the computational effort required to develop robust alignments of reference databases, particularly for marker genes like COI and 16S v4, which contain hundreds of millions of sequences in publicly available databases. However, recent advancements have leveraged advances in fast approximate likelihood approaches to assemble such trees (Pipes and Nielsen 2024b), opening the door to more widespread adoption. Lastly, *k*-mer based methods compare the similarity of small strings of nucleotides with length *k* (“*k*-mers”) to determine sequence identity. They include naïve Bayes algorithms like the Ribosomal Database Project (RDP) classifier (Wang et al. 2007) and the scikit-learn naïve Bayes machine-learning classifier used in QIIME2 (Bokulich et al. 2018), as well as other programs like Kraken2 (Wood and Salzberg 2014; Lu and Salzberg 2020) and sourmash (Irber et al. 2024). These alignment-free approaches to taxonomy assignment have been shown to be much more computationally efficient and often, but not always, more accurate than alignment methods (Bokulich et al. 2018; Hleap et al. 2021; Van Etten et al. 2023). *K*-mer based methods are sensitive to the composition of the reference database used and can be biased to species with more reference sequences (Robeson et al. 2021). The accuracy of a naïve Bayes classifier can be improved by including prior knowledge of species distributions and/or abundances. As such, if there are multiple hits to known taxa, the classification will be weighted toward the presumed more ecologically valid species (Kaehler et al. 2019; Gold et al. 2021; Mugnai et al. 2023).

A. Alignment sequence comparison

B. Phylogenetic comparison

1. Multiple Sequence Alignment

2. Phylogenetic Placement

C. K-mer sequence comparison

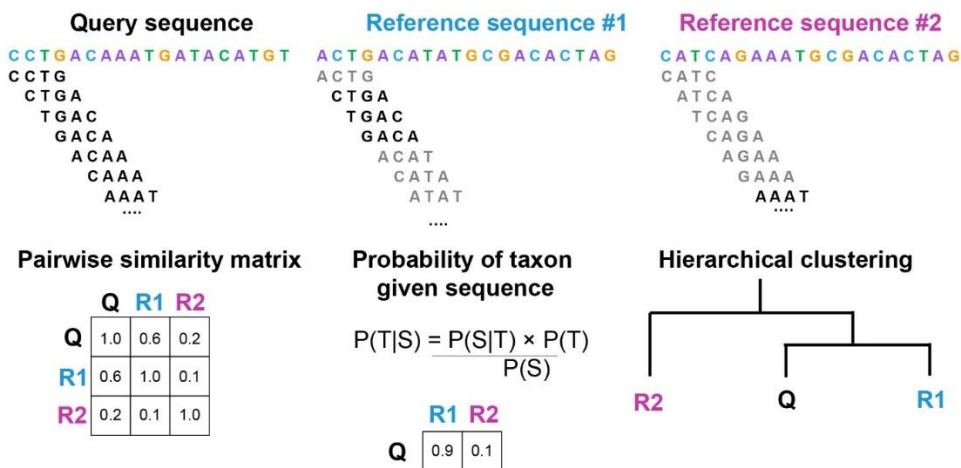

Figure 3: Three approaches to taxonomic assignment using reference sequences of known taxa. A) Alignment-based methods, which perform pairwise alignments and score the similarities based on nucleotide matches/mismatches and insertions/deletions. The highest-scoring pairwise alignment provides the assigned taxonomy. B) Phylogenetic based methods, which use multiple sequence alignments to generate phylogenetic trees. Taxonomy is assigned based on the closest evolutionary

relationship to reference sequences. Final taxonomic assignments from these methods can be made through consensus or lowest common ancestor approaches whose choices affect taxonomic assignments. C) *K*-mer based methods compare sequence composition using short strings of nucleotides of length *k*. In this example, all black *k*-mers are present in the reference sequence, and query sequences with more black *k*-mers in a query are therefore more similar to the reference. *K*-mer frequency profiles can be linked to specific taxonomic groups by generating similarity matrices or building machine learning classifiers from reference sequence databases, which are then used to assign taxonomy to the highest scoring reference sequence.

The choice of parameter values for each algorithm can heavily influence the final taxonomic assignments of each sequence. The choices for these parameters are particularly critical for the sequences that do not uniquely align to the reference database entries. For alignment and phylogenetic taxonomic assignment methods, parameters such as marker gene length, query coverage, and percent identity are critical (Figure 4), while for *k*-mer based classifiers *k*-mer size and confidence threshold should be critically evaluated. The 'consensus top hit method' stage of alignment-based methods selects a user-designated number of reference sequence hits over a user-designated percent identity. In instances where the taxonomy conflicts among the top hits, sequences are classified to the lowest taxonomic rank (a Lowest Common Ancestor or LCA method) that is shared among the top hits. Setting thresholds too high or too low can result in a high proportion of unclassified and incorrectly classified sequences. Phylogenetic-based assignment with the LCA approach may have an advantage in this regard, as it is not limited by the vagaries of taxonomic rank delineations (e.g., lumping versus splitting rates across genera and families), enabling the placement of query sequences among a set of references, often facilitating higher resolution at sub-rank levels.

Resolution

A. Marker Can Resolve Species			Match	Taxonomic Assignment

Figure 4. Key taxonomic classification issues for reference databases. Issues include A-C) **resolution**, the ability of known markers that can distinguish among target and non-target taxa; D-E) **comprehensiveness**, the presence of diverse potential species and congeners and all possible ASVs (amplicon sequence variants) within each taxon, accounting for population genetic variation at markers, F-G) **geographic relevance**,

whether the database includes species known to be found in your region or habitat, and H-I) **taxonomic curation** whether the database includes accurate species labels including up to date species nomenclature and trusted sequence annotations.

Reference databases

Reference databases contain sequences used for the identification of species. They range from large but poorly annotated public repositories (e.g., GenBank, RefSeq, ENA), to highly specialized 'bespoke' databases valid only for particular taxa at particular locations (e.g., FishCARD, (Gold et al. 2021). Examples of current databases are included in supplementary materials, [Table S1](#). Here we define four general types of reference databases: 1) comprehensive, uncurated public sequence repositories, 2) expert-curated reference databases, 3) uncurated, marker-specific reference databases, and 4) custom, curated reference databases. Comprehensive, uncurated public sequence repositories such as NCBI GenBank, ENA, and DDBJ serve as "parking lots" for user-submitted sequences, with the trustworthiness of sequences dependent on the accuracy of the user submissions. Although these public sequence repositories may contain errors (Leray et al. 2013; Schoch et al. 2020; Keck et al. 2023; Chorlton 2024; Renner et al. 2024), they remain highly used and comprehensive due to widespread international use by the research community.

To address quality concerns, researchers, institutions, and consortia have developed expertly curated reference databases with staff and resources dedicated to regular maintenance. These databases can have different communities of practice and levels of curation, and frequently include taxonomic curation, restriction to voucher specimens, and *in silico* sequence validation and removal of putative outliers. Many curated databases focus on either full mitogenomes or locus-specific nuclear genomes (e.g., BOLD, SILVA, GreenGenes), or target specific taxonomic groups, such as diatoms (Diat.barcode, rbcl) (<https://doi.org/10.1038/s41598-019-51500-6>), protists (PR2/18s), fish (MitoFish/12s), fungi (UNITES), and prokaryotes (SILVA). While typically derived from public repositories prior to curation, some accept direct submissions, potentially creating sequences exclusive to that curated database (e.g., BOLD).

Increasingly, software tools are enabling researchers to develop *marker specific databases* for diverse loci and target taxa in eDNA metabarcoding. These databases are typically marker-specific and range from uncurated (CRABS, Metataxa) to partially curated (RESCRIPT, rCRUX).

Each of the previously described types of databases can be further refined into custom, curated reference databases that may be specific to a single gene and geographic region of interest. For example, the FishCARD database includes only fish references from MiFish 12S sequences from the California Current Large Marine Ecosystem,

based on a comprehensive list of regional fish species developed through an extensive literature review. Similarly, the Chesapeake Bay Barcode Initiative leverages high-quality voucher specimens of regional invertebrate and fish species to add new marker sequences as new primer sets are developed. As bespoke reference databases are often generated for a specific project, they can sometimes lack dedicated support for long-term maintenance and can rapidly become outdated due to taxonomy updates and newly generated sequences.

We define taxonomic curation as the curation of the taxa and taxonomic hierarchy being used by a particular reference database. Different reference databases utilize distinct taxonomic backbones. For example, GenBank uses the NCBI taxonomic backbone, PR2 employs its own 9-level hierarchy, SILVA utilizes the Genome Taxonomy Database (GTDB), and UNITE relies on a sequence similarity-based taxonomy. The taxonomic backbones of expert-curated databases such as UNITE, PR2, and SILVA are informed by the expertise of their communities of practice, whereas NCBI Taxonomy is an amalgamation of user input that often includes outdated and unaccepted taxonomic names. We critically highlight that these taxonomic hierarchies are distinct, though often overlapping, with taxonomic backbones used by global biodiversity platforms like Global Biodiversity Information Facility (GBIF) and OBIS, which leverage the Aphia platform to integrate taxonomic information across Global, Regional, and Thematic Species databases. Efforts are underway to better unify taxa across the various taxonomic hierarchies (e.g., Biodiversity Information Standards TDWG). However, researchers today are challenged with navigating multiple existing taxonomic hierarchies. This results in new challenges as eDNA metabarcoding efforts increasingly use multiple marker loci simultaneously and thus may need to use multiple reference databases with different taxonomic hierarchies on the same sample, making synthesis of such datasets challenging.

Here, we highlight the need to acknowledge the advantages and disadvantages that a specific reference database or taxonomic hierarchy being used may have. We recognize that changing taxonomic backbones, along with increasingly expanded reference databases, present a monumental challenge for eDNA metabarcoding analysis and providing taxonomic assignments that follow Findable, Accessible, Interoperable, and Reproducible (FAIR) principles, as such classifications are not static and subject to change over time (Takahashi et al. 2025). Retaining and depositing representative OTU or ASV sequences is critical for updating taxonomic classifications as databases are updated.

Evaluating reference databases for trustworthiness is critical for enhancing the success and confidence of eDNA-based taxonomic assignments. Existing tools like GapDNA

can be used to conduct gap analyses to evaluate the comprehensiveness of a given reference database. Likewise, tools like TAXXI and tax-credit can be used to evaluate resolution for a given marker set (Robert C. Edgar 2018; Bokulich et al. 2018). To date, there are few tools to conduct systematic taxonomic curation of reference databases, with much of this work led by taxonomic experts that produce professionally curated reference databases like PR2 for protists, SILVA for microbes, FITS for fungi, and MitoFish for fishes. However, not all markers have dedicated research teams conducting taxonomic curation efforts and thus, researchers may need to curate their own reference databases appropriately.

In addition, the geographic relevance of reference sequences is often completed manually and requires extensive knowledge of the existing taxa within a biogeographic region. Determining geographic relevance of observed sequences and species is better suited for well-studied areas with comprehensive species inventories (e.g., fishes of the California Current Large Marine Ecosystem, (Gold et al. 2021); fish and invertebrates of Chesapeake Bay; freshwater fishes in Switzerland, (Blackman et al. 2023)). Researchers have also used global biodiversity observation databases to build more comprehensive, bespoke reference databases (O'Brien et al. 2024). The Ocean Biodiversity Information System (OBIS) and GBIF are two examples of publicly available species observation databases. However, similar to international sequencing repositories, these biodiversity databases have their own issues that may affect the trustworthiness of such biodiversity observations (Zizka et al. 2020). In addition, GBIF and OBIS also rely on different taxonomic hierarchies than GenBank or PR2 and thus require cross-walking of taxonomic references to accurately facilitate geographic curation. To date, no systematic tools exist to facilitate rapid geographic curation of species identifications from eDNA metabarcoding, highlighting the value of incorporating ecological and biogeographic expertise from regional and taxon-specific professionals in accurate interpretation of eDNA data.

It is also important to consider tradeoffs associated with using custom reference databases and post-classification processing versus expertly curated reference databases. Using the latter comes with a suite of advantages, as such databases often have been taxonomically curated, evaluated for their resolution, and systematically benchmarked. However, previous work has demonstrated the advantages of using custom reference databases that have been curated for geographic relevance (Gold et al. 2021; Pagenkopp Lohan et al. 2023; Mugnai et al. 2023) and have enhanced comprehensiveness (Arranz et al. 2020; Jeunen et al. 2023; Curd et al. 2024).

Reference databases are often subsetted for various reasons like speeding up ASV classification procedures or reducing the appearance of ASV misclassification. To

reduce the reference databases' size, full-length sequences and online repositories can be scanned with a particular primer pair to return only those taxa (and their amplicon sequences) that could (theoretically) be detected (cite rCRUX, QIIME2). In addition, it is important to dereplicate reference databases, especially for cluster-based classifiers, as algorithms can be biased toward overrepresented taxa. Dereplication efforts can also help identify marker resolution (e.g., which taxa have unique sequences). Example reference databases and their appropriate backups are included in Supplemental Information (Table S1).

Collectively, different methods of taxonomic assignment can impact the final output of species generated from sequence data (Richardson et al. 2017; Hleap et al. 2021; Van Etten et al. 2023), but the exact outcomes vary based on target organisms, marker gene, project goals, and software parameters. For example, database coverage for fishes may be very high for a specific study region, whereas for others (and many other taxa; e.g., microbes, plankton) there will be an unknown large number of taxa missing from the database and unresolved issues in taxonomic classification. We therefore hesitate to recommend a single “best practice” or database for taxonomic assignment. Instead, researchers should approach taxonomic assignments with caution and conduct systematic evaluations and rigorous benchmarking of the performance of taxonomic assignments. Species-level assignments should be critically evaluated, especially when high confidence is required for a detection, such as regulatory and management implications (Kelly et al. 2024).

We encourage more widespread *in vitro* and *in silico* benchmarking of marker gene sequence taxonomic resolution, when project resources allow. Comparisons of assignment methods and optimization of parameters can be performed on a chosen reference database using tools such as TAXXI (Edgar 2018), tax-credit (Bokulich et al. 2018), or the QIIME2 plugin RESCRIPt (Robeson et al. 2021). Mock communities relevant to target organisms can also be used as benchmarks for determining an optimal approach. In most cases, results can be validated to some degree using local ecological knowledge, different data streams (e.g., visual observations), or manual checks (e.g., manual sequence alignment with reference sequences of the annotated species). We suggest performing some or all of these validations when reasonable, but especially when results may be used for management or policy decisions that require high confidence and transparency. In all cases, each step of the analysis and all associated code should be reported for transparency and reproducibility.

Validating results

Identified species should be reviewed against expected and likely organisms in the region. This can be done during the sequence data processing as described above, using either a) a custom reference database curated for local species or b) a taxonomic

assignment method that preferentially weights assignment of local species (e.g. Kaehler et al. 2019). However, it may be important to consider the presence of unexpected taxa. If a detected species is not expected to be present in the system, several possibilities should be considered: 1) new detection of an organism not previously known to be living in the region, indicating previously unrecognized biodiversity or newly introduced species (e.g., invasive species, range shifts (Lohan et al. 2023); 2) detection of exogenous eDNA sources (e.g., wastewater, food processing facilities, ballast water, (Darling et al. 2021)); or 3) process-based erroneous detections arising from either low level contamination, sequencing artifacts, ambiguous sequences, or incomplete reference databases. Each of these is discussed in more detail below.

1) New detection of an organism, invasive species, or rare species

In order to determine whether a detection of an organism is new to a region, a comprehensive assessment of what is known to live in the region is needed. Long-term monitoring programs, peer-reviewed literature, agency reports, and local experts can be used to generate lists of expected species. Local and regional resources are often more reliable than national databases. Resources include OBIS, GBIF, Fishbase, USGS, and local agencies (e.g., state website). The expected species should include potential invasives and range expansions. A list of expected species (both native and non-native) can be generated using the local and regional resources above. Regional watchlists (e.g., USGS Nonindigenous Aquatic Species information resource, USDA Invasive Species Profiles List) can be used to screen for unexpected invasive species.

Invasive aquatic species are inherently a regional issue because non-native species always have a native range. This is especially true for the freshwater realm, which is more clearly partitioned. Invasive marine species, especially invertebrates, can be widely distributed, and some have uncertain origins (cryptogenic). Researchers and managers should be aware of the potential for erroneous detections of AIS and native species when reference sequences are not available or closely related species share identical barcode sequences. Taxonomic assignments of invasive, endangered, and otherwise protected or listed species can have severe management implications and thus should be associated with greater confidence requirements. As Carl Sagan noted, “Extraordinary claims require extraordinary evidence” (Tressoldi 2011). Thus, researchers should conduct due diligence in the taxonomic assignments of invasive and listed species, including conducting multiple different assignment approaches and evaluating the completeness and resolution of reference databases for such taxa and their sister species.

2) Exogenous eDNA Sources

Exogenous eDNA detection herein refers to DNA that is present in a sample, but likely does not represent a species living in the immediate sampled environment. These

molecules may be introduced during the sampling process (contamination), or may have been transported to the sampled environment by human or natural processes. Detection of these species should be reported and flagged or explained, when possible, to clarify the probable pathway into the sample. There are several ways DNA can be introduced, including transport by natural systems. DNA moves downgradient through natural transport systems such as currents, surface runoff, or wind. These detections are representative of the larger environmental system in the region, but may be misleading if presented in a list of organisms detected in a local ecosystem (Stolarz et al. 2024). It may be difficult or impossible to differentiate such detections from DNA generated by more localized sources. Nonetheless, eDNA practitioners should be wary of such potential exogenous sources of eDNA. The use of robust sampling designs, pilot studies, and local knowledge is paramount in ensuring accurate interpretation of eDNA signals.

3) Process-based erroneous detections

Capture, handling, and interpretation of eDNA is influenced by a complex interplay of environmental, physiological, and analytical processes that can result in erroneous detections of species that are not present in the environment (Harrison et al. 2019). Contamination can occur at any stage of the sampling process, introducing DNA from a species that was not present at a site (Goldberg et al. 2016). The use of non-template controls (e.g., blanks) at each stage of the workflow (sampling through PCR) aids in the identification of contaminating species and associated samples. In some cases, contaminating species may also be present in the sampled environment and thus careful consideration should be given to how such samples should be reported. Ambiguity in taxonomic assignments can occur because of poor resolution of a given locus or because of incompleteness of reference databases. Species with highly similar or even identical sequences in the amplicon region used for identification can be misidentified bioinformatically. As discussed above, different taxonomic classification algorithms can be more or less conservative in their approach to assigning taxonomy.

Addressing uncertainty - Filtering low counts, blanks

eDNA metabarcoding is a powerful method for detecting rare species, but low read counts in metabarcoding data present a challenge because it can be difficult to separate signal from noise. The relative penalty of a false-negative vs a false-positive detection will differ among projects, depending on the project objectives. Data filtering parameters can be selected to be more or less permissive based on these specific objectives of the study. For example, low read count detections can arise from low-level contamination or sequencing artifacts, even when best practices are applied. False positive detections are likely to increase when rare taxa are targeted (Sepulveda et al. 2020), and researchers and managers may have to adjust tolerance for false positive detections if high sensitivity for rare taxa is desired (Darling et al. 2021). This issue emphasizes the

importance of using complementary methods to confirm eDNA metabarcoding results, indicating expected detections of species of management concern (e.g., newly introduced species).

Detecting contamination

Gel electrophoresis is inadequate for assessing low-level detection, which may not show a strong signal in the form of a strong band on a gel. For more specific information on contamination sequencing and analyzing field, extraction, and PCR blanks may help researchers assess the risk of erroneous detection through low-level contamination and artifacts. If blanks are sequenced, there should be a clear protocol indicating how these samples are interpreted and follow-up actions. Alternatively, a more stringent threshold (higher read count) can reduce the risk of false positive detections, but may increase the risk of false negative detections.

Other approaches for detecting contamination include identifying the pattern of exact ASVs (not just taxa) across multiple samples, sites, and controls; eliminating samples or ASVs based on the number of observed reads to remove noise from datasets (e.g., remove singletons or samples with fewer than 10,000 total reads), and comparing the similarity of biological and technical replicates. Many of these approaches can be implemented through existing software designed to detect and remove contamination, like the R programs Decontam (Davis et al. 2018) and metabar (Zinger et al. 2021).

Comparing across replicate samples

Observing taxa in multiple replicates increases the confidence of detection. Replicates can be different: samples from the same time and place (same or different bottles), samples from the same place but different times, and multiple aliquots of the same sample all increase confidence in results; if an organism is detected in more than 1 replicate, it may be less likely to be an artifact or introduced as contamination. Increasing the number of samples at any point in the workflow also increases costs, so the value of additional samples must be balanced against the resources required to process samples. In cases where a high degree of certainty is required, replicate samples may be essential.

Confidence versus resolution tradeoffs

As highlighted throughout, assigning species names to eDNA metabarcoding-derived sequences involves a broad suite of choices that may influence which species are reported. Previous work has documented that these choices result in confidence versus resolution tradeoffs, where choices result in either higher confidence decisions with more conservative species identification (e.g., genus or family rank) or less conservative species-level assignments with lower confidence. For example, previous work found

that accuracy, overclassification, and misclassification rates increased with lower confidence score cutoffs in metabarcoding taxonomic assignment (Edgar 2018; Gold et al. 2021). Thus, selection of the optimal parameter metric is contingent on what metric, accuracy maximization, bias minimization, or a combination of the two, is being optimized. Given the broad range of applications of eDNA approaches, differences in project objectives, and tolerances for inaccuracy, no one-size-fits-all approach is available for assigning taxonomy to eDNA sequences. Thus, it is contingent on the eDNA practitioners to discuss and identify relative tolerances and project objectives *a priori* to project implementation to inform confidence versus resolution tradeoffs. Many tradeoffs can be eliminated or at least ameliorated with additional background information, such as identifying priority target taxa, ensuring complete and comprehensive reference sequences, conducting *in silico* and *in vitro* validation and benchmarking of approaches, and delineating what trustworthiness of eDNA data results look like.

Implications of workflow process for species identification

Table 1 presents examples of commonly encountered issues related to species identification. Generally, each step in the processes described here has an impact on downstream steps and the resolution of species. Primer selection broadly constrains the organisms that are amplified, from domain (e.g., bacteria vs eukaryotes) to species-level resolution. PCR and sequencing steps must be carefully adhered to prevent erroneous detections from contamination, or loss of species due to degradation. Bioinformatics encompasses multiple steps to filter, search, and assign taxonomy. Overly stringent criteria in these steps may remove taxa or reduce the ability to assign taxonomy to species level. Less stringent criteria may result in incorrect assignment of similar species. Finally, communication of results must clearly convey any uncertainties associated with taxonomic assignment, such as similar matches to multiple species, to avoid misunderstanding by end users.

Dissemination and Communication

All environmental monitoring methods have some underlying uncertainty; closely related species may be difficult to distinguish visually, taxonomy may be unresolved, net size or capture method may screen out some organisms, and very rare species may be essentially undetectable in some environments (Kelly et al. 2017). Monitoring applications relying on molecular methods have unique factors that influence species identification in ways that may be unfamiliar and require additional interpretation and end user support (Gold et al. 2021; Kelly et al. 2024). Careful consideration of the factors discussed above can reduce ambiguity, but species assignments from metabarcoding data will always involve some degree of uncertainty until all of life has been described and characterized. Helping resource managers and other users

understand the source and degree of this uncertainty is critical for responsible decision-making and to support trust in the data.

Thus, it's important to note and communicate the underlying uncertainty. Providing clear information on the methods and caveats associated with a given species identification helps users interpret the data correctly and decide on any necessary further steps. Researchers should also consider context-dependent reporting of eDNA metabarcoding observations. The choice between reporting a consensus taxonomic level or the overlapping species that comprise a taxonomic assignment depends on the specific requirements of the downstream analysis. If end users, such as resource managers or conservation biologists, require detailed species-level data, then it may be worth listing all possible candidate assignments for a given sequence. For fisheries management, conservation planning, or ecological studies, knowing the possible species, even with some uncertainty, can guide more targeted follow-up studies or interventions. In contexts where precise species-level information is critical (e.g., for detecting invasive species or ensuring sustainable fishing practices), providing the list of candidate species may be more informative.

Following FAIR and open science principles, scientists generating metabarcoding-based data sets must provide users with materials explaining how eDNA data is generated, and where sources of error come from if requested. Data reports should contain all information needed to understand the results. Here we suggest that, in addition to the MIEM, FAIRe, and EMMI reporting standards, eDNA metabarcoding research papers for conservation and management also include:

- Include a "Key Findings and Cautions" Section which summarizes major results, major results in plain language, but flags uncertainties clearly. For example, 'Some detections (e.g., family *Gadus*) could not be reliably assigned to species due to marker limitations. Follow-up visual surveys are recommended to confirm species identity where management action is needed.'
- Quality control and quality assurance flags are used to indicate both the level and source of uncertainty. For example, if a sequence matches multiple closely related species, but only one is likely to be present, a researcher may choose to report only the taxonomy of the geographically relevant taxa. Here, the researcher should report the flag and when and where it was applied. Depending on project needs, users may choose to use the geographically relevant species-level assignment or rely only on genus-level assignment. Flags should indicate the level of confidence in the reported assignment and why that confidence is assigned, e.g., high confidence at species level, vs at genus only. Visualizations can help managers understand certainty levels. For example,

color-coded detection maps or stacked bar charts showing relative read abundance grouped by uncertainty.

- Explain when filtering criteria, such as minimum read counts or detection across replicates, were applied and how that affects results. These criteria may differ depending on project goals: when trying to detect a rare species, lower thresholds may be appropriate. All results should be available in some appendix or portion of the report to avoid filtering very rare species.
- Provide Actionable Guidance Despite Ambiguity. In many cases, data tables are generated by a contracted lab and cannot be tailored to meet specific project needs. In this case, general recommendations can be applied, such as reporting at genus level if resolution of an ambiguous species is not important to the study goals.

Conservation & Management

As eDNA is increasingly used by a wider community of resource managers and other stakeholders, metabarcoding offers a powerful tool for detecting species presence and biodiversity in aquatic systems, but species identification from sequence data is influenced by a range of methodological and interpretive decisions. This framework outlines best practices for each stage of the workflow—primer selection, lab handling, bioinformatics, taxonomic assignment, and results communication—with a focus on transparency and aligning decisions with project objectives. By acknowledging limitations such as incomplete reference databases, contamination risks, ambiguous sequences, and detection biases, researchers can better interpret results and communicate findings to stakeholders. Replication, data validation, and the use of confidence flags or structured annotations can support responsible data use, especially in conservation, management, or regulatory contexts. Ultimately, this guidance can improve the accuracy, reliability, and usability of eDNA species identification while fostering trust and understanding among diverse end users.

Methods and approach used in this document

This paper focuses on portions of the metabarcoding workflow that are key to identifying species, but there are many additional, important aspects to metabarcoding-based ecosystem assessment that are not covered here. The use of eDNA to quantify organism abundance or population size, population genetics, and phenolic expression are emerging methodologies with high potential usefulness, but are not discussed here.

The discussion and examples presented here are drawn from the experience of the authors, which is primarily in aquatic systems, but are broadly applicable to metabarcoding-based species identification in any taxonomic group. The document was conceived and written by all authors, with sections and figures provided by different

authors. AI tools were used in the later stages of document preparation for final copy editing and reference management.

Issue	Environmental	Contamination	Laboratory		Bioinformatics & Taxonomic Assignment		
			Primer Choice	PCR and Sequencing	Sequence QC & Dereplication	Classification	Reference Database
Non-native species detected	Non-native species is present in sampled environment. Or DNA from anthropogenic sources present	Laboratory contamination in extraction or amplification step	Gene region can not distinguish among native and non-native species	PCR artifact generates highly similar ASV to correct species / tag jumping from other samples on sequencing plate	QC not stringent enough to exclude artifacts	Classifier method accepts best match not perfect match.	Reference database lacks sequence from true species but contains identical sequence from non-native organism
Species-level taxonomy not identified			Primers do not amplify target species or gene region cannot distinguish among species		Dereplication collapses multiple true unique sequences (e.g. OTU clustering)	Selected classifier and/or parameters lack resolution to delineate species.	Multiple species have identical reference sequences
Species known to be present is not detected	Species is small component of sampled community and not captured in eDNA sampling		Primers do not amplify target species or gene region can not distinguish among species	PCR amplification bias leads to lack of detection. Too few reads sequenced to capture full diversity.	QC too stringent and excludes true ASVs	Selected classifier and/or parameters lack resolution to delineate species.	Reference database lacks sequence from true species

Solutions	Environmental	Contamination	Laboratory		Bioinformatics & Taxonomic Assignment		
			Primer Choice	PCR and Sequencing	Sequence QC & Dereplication	Classification	Reference Database
Non-native species detected	Limit sampling to areas not impacted by known anthropogenic eDNA sources	Ensure proper sterile technique in field and laboratory work. Use multiple negative controls and monitor sequencing quality. Carefully track sample handling.	Use primers that have been validated for your target both in silico and in vitro.	Use methods like dual unique indices to limit tag jumping and DNA polymerases with low error rates.	Conduct stringent QC at multiple stages of pre and post processing. Apply abundance/read thresholds or replicate-based filtering, informed by ecological plausibility and best practices.	Independently validate taxonomic assignments using other approaches. Provide “confidence flags” or a tiered approach to species reporting.	Ensure local reference database includes known non-native species. If needed generate additional reference sequences to enhance coverage.
Higher taxonomic ranks observed (e.g. Genus or Family level ID)			Use primers that have been validated for your target both in silico and in vitro.		Use unique ASVs without clustering as taxonomic identifiers	Conduct classifier and/or parameter optimization for maximum resolution. Perform sensitivity analyses on classification parameters.	Conduct taxonomic and geographic curation of reference databases.
Species known to be present is not detected	Sample higher volume increase replication use appropriate filter size		Use more specific primer to organism of interest and which amplifies region that can distinguish between closely related taxa	Increase sequencing depth and/or replicates, alter PCR parameters to be more strict or lenient depending on direction of bias (towards or against target taxa)	Alter bioinformatic parameters to be more tolerant of rare sequences	Conduct classifier and/or parameters optimization to ensure maximum possible resolution. Limit reference database to local species sequences.	Barcode local species and add to reference database. Include closely related global species in database and look for similar sequences.

Table 1. Common issues encountered in species identification. Likely causes and potential solutions are listed here and discussed in more detail in the text.
