Abstract

Merten’s carpet sea anemone, *Stichodactyla mertensii*, is the largest known sea anemone species in the world, regularly exceeding one meter in oral disc diameter. A tropical species from the Indo-Pacific, *S. mertensii* drapes prominently over coral reef substrates and is a common host to numerous species of clownfishes and other symbionts throughout its range, which extends from the Red Sea through the Central Pacific Ocean. Long thought to reproduce via sexual reproduction only, recent genetic evidence suggests it may rarely reproduce asexually as well, although this process has never been confirmed through direct observation and the mechanism is yet to be described. Here, we directly observed and documented in situ asexual fragmentation via budding, in real time, by a Red Sea *S. mertensii* in a turbid inshore reef environment. While asexual reproduction is not unusual in sea anemones as a group, it is typically expected to be uncommon for large-bodied species. Herein, we describe *S. mertensii* fragmentation, provide high resolution images of the event from the Saudi Arabian coastline at multiple time points, and confirm asexual reproduction for this species.

Keywords: Sea anemones, Indian Ocean, Actinians, fragmentation, reproduction, clonality

Introduction

Asexual reproduction is common in sea anemones (Anthozoa: Actiniaria), which have evolved a variety of different asexual modes including pedal laceration, binary fission, longitudinal fission,
and budding (reviewed by Shick 1991). Asexual reproduction can lead to small clusters of two or three anemones up to expansive clonal aggregations of hundreds of individuals. Clonality can thus make important contributions to sea anemone population dynamics, especially for tropical species that serve as symbiotic hosts to a diverse suite of fishes and other invertebrates.

The Red Sea contains thousands of kilometers of fringing coral reef systems inhabited by tropical sea anemones, the largest of which serve as symbiotic hosts to clownfish. Yet only recently has there been clarity on the diversity of host anemone species that inhabit this region (Bennett-Smith et al. 2021). The largest species found in the Red Sea, *Stichodactyla mertensii*, is the largest known anemone species in the world, but has historically not been known to this region until only recently (Bennett-Smith et al. 2021). Although it is also possible that a range expansion has occurred, recent widespread documentation on surveys along the entire eastern coastline of the Red Sea indicates *S. mertensii* is native to the region but undescribed as the result of misidentifications in the literature (Bennett-Smith et al. 2021). In either case, despite *S. mertensii*’s widespread occurrence in the Red Sea, there have been few studies concerning its ecology or life history.

*Stichodactyla mertensii* is one of ten described clownfish-hosting anemone species found on Indo-Pacific coral reefs (reviewed by Titus et al., 2019). Only two, *Entacmaea quadricolor* and *Heteractis magnifica*, are known to reproduce clonally- a process well known to those in the aquarium trade who regularly propagate these species through binary fission by cutting the oral disc in half, resulting in two individuals. In the wild, *E. quadricolor* and *H. magnifica* regularly form clonal aggregations throughout its range via binary fission (Dunn 1981).

*Stichodactyla mertensii* are thought to reproduce sexually, not asexually, following the generalization that it has only ever been found solitarily and that smaller facultatively clonal animals are more likely to reproduce asexually versus their larger counterparts (reviewed by Titus et al. 2017). Recent work in the Red Sea however, has indicated low levels of potential clonality in *S. mertensii* populations through genetic sampling. Out of 122 individuals sampled by Emms et al. (2019) two were determined to be potential clones and both were found in waters surrounding or adjacent to the Arabian Peninsula (Saudi Arabia & Djibouti). Direct confirmation and mechanisms for asexual reproduction remain unknown. Here, for the first time, we observed fragmentation via budding from the column in real time in a Red Sea *S. mertensii*. We photographed the specimen at several time points to track its reproduction *in situ*. This evidence offers insight into the reproductive mechanisms of clonality in this species and expands our knowledge of reproductive modes for the clownfish-hosting sea anemones.

**Materials and Methods**

We conducted initial surveys on SCUBA near the campus of the King Abdullah University of Science and Technology (KAUST) in December 2021. During these surveys, we encountered several host anemone species, including *E. quadricolor* and *S. mertensii*.

To determine the identifications of host anemones located, we noted external morphological characteristics and used dichotomous keys from Dunn (1981) and Fautin and Allen (1992). Morphological characteristics that were used in identifying host anemones in the field include: the size and shape of the oral disc (flat, undulating, balled around the tentacles); the size, shape, color, and prevalence of verrucae (warty projections on the column) towards the pedal disc; the size, shape, density and uniformity of tentacles throughout the oral disc; the color patterning on the margins of the oral disc; the substratum in which the pedal disc was anchored.
(sand, rockwork, or rubble); and the coloration and appearance of the mouth. In the case of *S. mertensii*, this species has a large, flat oral disc, rounded, bulbous, tentacle tips, longer tentacles around the mouth than the periphery of the disc, and conspicuous verrucae along the column extending to the pedal disc.

One anemone identified as *S. mertensii* was observed in the process of asexually fragmenting via column budding. This individual was subsequently GPS marked, located at coordinates: 22° 16' 41.32" N, 39° 3' 54.23" E (Figure 1). The anemone was photographed *in situ* with a Canon R5 camera inside a Nauticam underwater housing, with two Sea and Sea underwater strobes.

After our initial observations, we returned to this location again in February 2022. We followed the same procedure and again photographed and measured the individual on SCUBA, with the same equipment.

### Results

#### Description

**Initial Observation:**

The individual that was observed had two separate budding locations, both on the column of the animal (Figure 2, Figure 3). When first observed (December 2021), one fragmentation bud was already recognizable as a separate individual, around 6 cm in length extending outwards with tentacles fully developed, although it was still attached to the column. The other bud was small, less than 2 cm, and newly formed with tentacles not extended (Figure 3A).
Second Observation:

The second observation was made on February 11, 2022 (33 days after the first observation). The larger of the two fragmentation buds had grown to an oral disc diameter size of ~12 cm, an increase of about 6 cm in oral disc diameter (Figure 2B, 2C). The smaller of the two fragmentation buds had grown from an initial disc diameter size of less than 2 cm to around 5 cm, an increase of 3 cm (Figure 3B).

Notably, the larger of the two fragmentation buds appeared to be much closer to separating from the parent entirely, and was only connected to the column by a thin stalk (Figure 2D).

Figure 2 In situ images of asexual reproduction of *Stichodactyla mertensii* on an inshore reef near Thuwal, Saudi Arabia. A) The parent *S. mertensii* individual, with two *Amphiprion bicinctus* symbionts. B) Top view of the parent individual (left, with anemonefish) and newly forming anemone bud (right). C) Anemonefish recruit (circled) in newly forming anemone bud. D) Cross section of the reef rockwork, showing the column of the anemone where the new fragmentation branches from.

Conclusions

These observations are the first of in situ asexual reproduction of *Stichodactyla mertensii* (and the first of any carpet anemone species in the Red Sea) yielding insight into the mechanisms by which these species reproduce clonally. Interestingly, *Stichodactyla mertensii* is not previously known to form clonal aggregations - a recent survey effort covering several thousand km of Red Sea reefs did not reveal a single aggregation of any carpet anemone species (Bennett-Smith et al. 2021). Similarly, other large clownfish-hosting species from the genus *Stichodactyla*, *S. haddoni* and *S. gigantea*, do not form aggregations of individuals nor are they thought to reproduce asexually. However, Titus et al. (2019) found *H. magnifica*, a species well-known to reproduce asexually, to be well nested within a broader clade containing the members of the genus *Stichodactyla*. Additionally, *S. helianthus*, a smaller carpet anemone species found on coral reefs in the Tropical Western Atlantic is a clonal species as well. Thus, it’s possible that this reproductive mode is under-described in the Indo-Pacific members of the genus *Stichodactyla*. Our observations in the Red Sea confirm that *S. mertensii* is the third species of clownfish hosting sea anemone to reproduce asexually, along with *E. quadricolor* and *H. magnifica*. The asexual reproductive strategies of other host anemones from the Red Sea and elsewhere in the Indo-pacific, including *Stichodactyla haddoni*, *S. gigantea*, *Heteractis aurora*, and *H. crispa*, *H. malu*, and *Macrodactyla doreensis* also remain unclear. Increased observational effort and further molecular work on this group may clarify these questions, which have downstream implications for a range of host anemone-associated taxa.

Acknowledgments

We thank the King Abdullah University of Science and Technology Coastal and Marine Resources Core Lab for providing assistance in the field. Thank you to Nathalia Delgadillo Ordonez, Ines Raimundo, and Viktor Nunes Peinemann for accompanying the initial survey dives.
